Spatial and Temporal Responses of Arterial and Venous Blood Volume Changes

Introduction

Total cerebral blood volume (CBV) -weighted fMRI (assessed with a susceptibility contrast agent) has shown significantly improved sensitivity vs. BOLD fMRI to sites of neural activation, with largest signal changes appearing at the middle of the cortex (1,2). The intensity of capillary density and metabolic responses are known to be highest. Arterial cerebral blood volume (CBV) changes (accessed with an arterial spin-labeling technique) showed that increases in CBV during neural activation originate mainly from arterial rather than venous blood volume changes (3). CBV responses (measured with a non-invasive magnetization transfer (MT)-varied fMRI technique) exhibited the highest signal change at the middle of the cortex (4) and similar to CBV responses. However, the spatial distributions of both responses have not been compared in the same animals. CBV responses have been observed as two components, an early rapid rise, followed by a prolonged slower response (5,6). It might be caused by different temporal contribution between arterial and venous volume changes, and it has not been investigated. In this study, functional CBV and CBV changes were measured in the same animals with MT-varied fMRI and contrast-agent fMRI techniques, respectively. Temporal characteristics of ΔCBVa and ΔCBVt were compared and temporal changes in cortical depth profiles were determined in order to identify the sources of early and late contributions to CBV responses.

Methods

Four female adolescent cats weighing 1.0-1.5 kg were studied on a 9.4-T MRI (Varian) system using only a single surface coil. Throughout the experiments 0.9-1.1% isoflurane-anesthesia was administered with an air/O2 mixture to maintain a total O2 level of ~30%. Binocular full-field visual stimuli were presented with square-wave high-contrast moving gratings (2 cycles/s) with 0.15 cycles/degree of spatial frequency during 40-s stimulation. Animals were maintained within normal physiological ranges. General imaging parameters were FOV = 2.0 x 2.0 cm², slice thickness = 2 mm. ΔCBVa and ΔCBVt fMRI was performed by GE-EPI with in-plane resolution = 312 μm x 312 μm, flip angle = 20° and TR = 1 s. For ΔCBVa fMRI (TE = 20 ms), the targeted MTR values (= 0, 0.3 and 0.6, in randomized order) in gray matter were achieved by adjusting the power level of MT-inducing RF pulses (+5 kHz off-resonance). For each pixel, normalized stimulation-induced signal changes with MT (ΔSMT/S0) were linearly fitted against normalized baseline signal with MT (SMT0/S0), and ΔCBVt was obtained from the intercept. For ΔCBVt fMRI (TE = 10 ms), 7-15 mg/kg monocrystalline iron oxide nanoparticles were injected, and stimulus-induced percentage CBV changes were calculated as previously described (7). High-resolution T1-weighted anatomical images were obtained from the same slice to identify brain structures by the two-segment turbo-FLASH technique with in-plane resolution = 156 μm x 156 μm, flip angle = 10°, intersegment duration = 4 s, inversion time = 1.4 s, and TE = 5 ms. Cortical depth profile analysis for layer specificity was performed in area 18 within the visual cortex as a follow-up: a quadrangular region spanning the cortical depth (from surface to white matter) was defined in each hemisphere, and each of these quadrangles were subdivided into 11 contiguous ROIs at varying depths from the cortical surface (1).

Results and Discussion

High-resolution T1-weighted imaging clearly shows a hyperintense cortical layer, which is likely to be the myelin-rich stripe of Gennari (black dashed line in Fig. 1A). Visual stimulus-induced ΔCBVa and CBVt percentage change maps (Figs. 1B and 1C, respectively) show that highest signal changes (yellow pixels) in the cortex generally appear within the overlaid black dashed lines, indicating that the highest arterial and total CBV changes occur within layer IV. Cortical depth profiles (n = 4) plotted for each 10-s time period during stimulation show a trend toward increasing sharpness (i.e., an increase in signal specificity ratio of layer IV vs. surface regions) between the 0-10 s vs. all later periods for both for ΔCBVa (Fig. 1D) and ΔCBVt (Fig. 1E); this trend was consistently observed in each individual animal, and is similar to our previous findings (4,8).

Averaged time courses from the intracortical regions show an early rapid rise in CBVa and CBVt responses (Fig. 2A). Data was smoothed by three point moving average calculation. For this comparison with ΔCBVa, ΔCBVt (%) was first converted from a percentage change to ml/100 g; the lower limit of baseline CBVa (ml/100 g) was determined by assuming that maximum ΔCBVa = maximum ΔCBVt ≈ 4 ml/100 g, which is also a reasonable match with our previously quantified CBVa value (3). Venous blood volume change (ΔCBVt) was then calculated by subtracting ΔCBVt from ΔCBVa (Fig. 2B). It appears that ΔCBVt slowly increase during the entire stimulation period. The current data could be interpreted as reflecting an initial rapid arterial vasodilation, with slower prolonged venous dilation resulting from increased venous pressure associated with arteriole vasodilation.
