**Introduction:** Nanostructured inorganic nanoparticles and core-shell structures can be used as MRI contrast agents with the advantages of flexible surface modification characteristics [1]. Manganese based nanoparticles have potential as agents that can be “activated” when taken into cells. For example, Mn oxides or Mn carbonates are insoluble at pH 7 but dissolve to release Mn<sup>2+</sup> at the lower pH found in the endosome-lysosome pathway. The dissolution of Mn based particles in an acidic environment leads to large enhancement of the T<sub>1</sub> relaxation rate [2]. In addition, Mn<sup>2+</sup> can leave the endosome-lysosome pathway to fill the entire cell leading to a much larger volume distribution of the contrast agent [2]. It would be advantageous to be able to control the rate of dissolution of Mn based nanoparticles to control T<sub>1</sub> contrast signals, *in vivo* with time. To this end, five different coatings on MnO nanocrystals have been tested to study the release rate of the Mn<sup>2+</sup> ions and change in relaxivity at pH 7 compared to pH 5.

**Experiments:** Highly monodisperse, single-phase, MnO nanocrystals (NCs), ~10 nm in diameter, were prepared by chemical routes and their magnetic properties were extensively characterized [3]. Mercaptosuccinic acid (MSA), poly(maleic anhydride-alt-1-octadecene) (PMAO), Pluronic F-127 (PF127), PMAO-PEG and SiO<sub>2</sub> were then used, respectively, to transfer native hydrophobic particles to aqueous solutions for biocompatible applications. T<sub>1</sub> relaxivities of these particles coated with five different molecules were determined by phantom experiments. In addition, particles were injected into the brain in the region of the thalamus [4], in order to test the rate of dissolution and subsequent neuronal tracing of the released Mn<sup>2+</sup>. Five rats received 100 nL of 16.8 mM MnCl<sub>2</sub> solution into the left hemisphere and MnO@SiO<sub>2</sub> solution into the right hemisphere. Images were acquired with an 11.7 T/31 cm horizontal bore magnet (Magnex Scientific Ltd., Abingdon, UK), which was interfaced to a Bruker Avance console (Bruker Biospin, Billerica, MA, USA). A Magnetization Prepared Rapid Gradient Echo (MP-RAGE) sequence was used. Sixteen coronal slices with FOV=2.56×2.56 cm, matrix 256×256, thickness=0.5 mm (TR=4000 ms, Echo TR/TE= 15/5 ms, TI=1000 ms, number of segments=4, Averages=8) were used to cover the area of interest at 100 μm in-plane resolution in 34 min.

**Results:** MSA-, PMAO-, PF127-, and PMAO-PEG- coated nanoparticles had relatively high relaxivities in PBS buffer solutions at pH 7 (1.8-2.5 s<sup>-1</sup>mM<sup>-1</sup>) and dissolved very quickly at pH 5. For example, it took ~20 min to reach relaxivity of 6.94 for MSA coated particles at pH 5. SiO<sub>2</sub> coated particles showed the smallest relaxivity (0.29 s<sup>-1</sup>mM<sup>-1</sup>) at neutral pH, which was stable over time. The MnO@SiO<sub>2</sub> nanoparticles had the best dynamic range for contrast change when the pH was lowered. Time dependent relaxivity measurements (Fig 1), at pH ~5.0 in acetate buffer solution of MnO@SiO<sub>2</sub> nanoparticles showed values increasing to 2.44 s<sup>-1</sup>mM<sup>-1</sup> by 53 min to 6.1 s<sup>-1</sup>mM<sup>-1</sup> after 75 hours. This final relaxivity is equivalent to MnCl<sub>2</sub> indicating that the particles had completely dissolved. The release rate of Mn<sup>2+</sup> ions was faster for the first 5 hrs, subsequently slowing down after 10 hrs. MP-RAGE images of the rat brain (Fig 2) showed that the signal intensity at the injection site of MnO@SiO<sub>2</sub> particles (left sides in images) increased with time consistent with the slow dissolution rate measured in vitro. The signal at the site of MnCl<sub>2</sub> injection (right sides of images) was elevated at the first image after injection and began to decrease slightly due to tracing of the Mn<sup>2+</sup> ions to different parts of the brain.

**Conclusions:** Different coating for MnO nanoparticles can affect the T<sub>1</sub> relaxivity at pH 7 and the rate of dissolution at pH 5. MnO@SiO<sub>2</sub> particles had the lowest pH 7 relaxivity and the slowest dissolution rate at pH 5 in vitro. *In vivo* MRI of MnO@SiO<sub>2</sub> particles injected into the brain showed time-dependent signal changes consistent with the in vitro rates. The MnO@SiO<sub>2</sub> particles show the best potential for delaying the release of MRI contrast until specific biological processes have occurred, such as endocytosis.
