Introduction: Lithium (Li) is an elemental cation used in the treatment of bipolar disorder. It is presumed to work intracellularly, but the fraction of intracellular Li in the brain in vivo is not known. Shift reagents can separate intracellular and extracellular NMR signals of cellular preparations in vitro, but are typically precluded from in vivo studies of brain. Lithium-7 MR is the only technique available for noninvasively measuring the concentration of Li in the brain in vivo. We have reported localized $^7$Li MRS studies of total Li concentration and spin relaxation in rat brain in vivo. At high Li doses, unambiguous biexponential $T_2$ behavior can be readily observed. Although intrinsic biexponential transverse spin relaxation might be expected for a spin-3/2 nucleus in a biological system, Li's spin relaxation is only weakly quadrupolar, and intrinsic biexponential relaxation has not been observed either intracellularly or extracellularly for Li in a range of biological systems. Assuming the same holds true for the brain in vivo, then biexponential behavior in a localized Li MRS experiment, if observed, can be attributed to separate signals from the intracellular and extracellular (plus CSF) compartments. The two-compartment (intra-/extracellular) assumption is common in MR studies of brain. Because of increased binding, cationic $T_2$ is expected to be lower intracellularly than extracellularly. Li binds more strongly to the inner rather than the outer leaflet of the plasma membrane due to the higher concentration of anionic phospholipids in the inner leaflet. In our initial work using this approach, we estimated intracellular Li in rat brain in vivo under a variety of MRS and dosing conditions at 4.7 T. Here we report biexponential $^7$Li $T_2$ relaxation studies in rat brain at 7 T with isotopically enriched $^7$LiCl to determine the compartmental distribution of Li as a function of brain Li concentration, and to assess reproducibility and performance of a simple linear approximation to estimate intracellular Li from monoexponential $T_2$ decay.

Methods: Thirteen rats (212±25 g) were dosed IP with isotopically enriched $^7$LiCl [4 x 5 (or 3.25-3.5) meq/kg over 2.0 days]. A voxel (0.43-0.47 ml) totally within brain was chosen using $^1$H axial and sagittal 2D-RARE MR images on a Bruker 7-T Biospec spectrometer. The localized Li $T_2$ s were measured using PRESS with TR of 5 s and 12 TE values from 3.75 to 300 ms at 116.7 MHz. Spectral acquisition, localization, and curve-fitting details were essentially identical for all animals. $^7$Li $T_2$ decay curves were fit to a biexponential function using the nonlinear estimation module in Statistica (Statsoft Inc., Tulsa OK). A biexponential fit explained substantially more of the statistical variance (97.8±2.4%) than the alternative monoexponential fit (85.6±3.4%). As expected, the % of the variance explained by the biexponential fit correlated with brain Li concentration (r=0.75). The intracellular fraction of Li was also estimated as previously described using the linear interpolation: % intracellular = 100($T_{2i} - T_{2mono}$)($T_{2o} - T_{2i}$), where the intracellular ($T_{2i}$) and extracellular ($T_{2o}$) relaxation times were averages of the short and long components, respectively, of the biexponential decay, and $T_{2mono}$ is the $T_2$ determined using a monoexponential fit.

Results: The results are given in the Table. The dosing regimen produced brain Li concentrations ranging from 1.1 to 6.1 mM. The average $T_{2o}$ of 14.8±4.3 ms was similar to our earlier result, whereas the $T_{2o}$ of 295±61 ms was roughly double the earlier result. The intracellular fraction varied from 37.3 to 64.8%. The intracellular fraction of Li determined by biexponential fit did not correlate with brain Li concentration or $T_{2o}$, although it did correlate with $T_{2i}$ (r=0.57) and $T_{2mono}$ (r=0.68). Moreover, these results did not differ between groups having high (cases 1-10) and low (cases 11-13) brain Li concentrations. The interpolation method for estimating % intracellular Li from monoexponentially fitted $T_2$ data was tested on these 13 cases. $T_{2mono}$ varied from 73 to 179 ms. The interpolated results were on average about 16% higher than, and significantly correlated with (r=0.68), the direct biexponential results.

Discussion: This work supports our previous conclusion that, unlike for Na, a substantial fraction of Li enters the cell in vivo. This is consistent with an intracellular mechanism of action of Li in bipolar disorder. Interestingly, the intracellular fraction of Li does not depend on the overall concentration of Li in brain, indicating that the cell does not maintain a constant intracellular Li concentration. The interpolation method for a monoexponential fit may provide a semiquantitative estimate of intracellular Li for cases where biexponential decay is not observed. It is necessary to confirm that single-compartment spin relaxation of $^7$Li is monoexponential in brain in vivo, since some intra-/extracellular distributions are close to 60:40, which is the ratio expected for pure intrinsic biexponential $T_2$ relaxation.
