**Target Audience:** Scientists interested in hyperpolarized gas magnetic resonance imaging (MRI) of the aging lung

**Purpose:** Previous work has shown a relationship between age and hyperpolarized 3He MRI apparent diffusion coefficients (ADC) suggesting that there are changes in the lung microstructure that increase alveolar volume during the aging process. However, it is unknown whether these changes in the ADC gradients in the superior-inferior (SI) and anterior-posterior (AP) direction also occur during the aging process.

**Previous studies have demonstrated that 3He ADC anterior-posterior gradients were thought to be attributed to regional gas trapping.** 3He ADC anterior-posterior gradients are were also shown to normalise in COPD following salbutamol administration-consistent with the relief of regional gas trapping (2). We hypothesized that the anterior-posterior gradient is reduced during the aging process and that there is a significant relationship between the anterior-posterior gradient and age. Therefore, our objective was to quantitatively evaluate the anatomical distribution of ADC using hyperpolarized 3He MRI in healthy elderly never-smokers.

**Methods:**

**Subjects:** Healthy elderly never-smokers (≤ 1 pack year smoking history) between 60-90 years of age with no history of acute or chronic respiratory diseases provided written informed consent to the study protocol approved by the local research ethics board and Health Canada. All subjects underwent spirometry, cycle ergometry, and hyperpolarized 3He MRI at a single study visit.

**Image Acquisition:** Imaging was performed on a whole body 3.0 Tesla Discovery 750MR (GE, Milwaukee, WI) with broadband imaging capability as previously described (1). For 3He MRI, a polarizer system (Helispin™) was used to polarize 3He gas. Hyperpolarized 3He MRI diffusion weighted images were acquired during breath-hold of a 1L He/N2 mixture obtained using a fast gradient-recalled echo method (FGRE). Two interleaved images (14s total data acquisition, TR/TE/flip angle = 7.6 ms/3.7 ms/8°, FOV = 40 x 40 cm, matrix 128 x 128, 8 slices, 30 mm slice thickness), with and without additional diffusion sensitization (G = 1.94 G/cm, rise and fall time = 0.5 ms), gradient duration = 0.46 ms, Δ = 1.46 ms, b = 1.6 s/cm²), were acquired.

**Image Analysis:** Anatomical differences in ADC were quantified in the five central slices by: 1) calculating the absolute ADC difference for AP slices (ΔAP) and SI ROI (SI); and 2) measuring the ADC gradient for AP slices (AP-gradient) and for SI ROI (SI-gradient) in cm²/s/cm. AP-gradient was defined as the slope of the line that described the change in ADC in AP as a function of distance in centimeters over the five central slices and was calculated using the mean ADC of whole lung slices. The SI-gradient was defined as the slope of the line that described the change in ADC over the upper, middle, and lower ROIs in the five center-most slices. AP-gradient and SI-gradient were obtained from the slope of five points and three points, respectively, using linear regression. We also evaluated relationships between ADC gradients and spirometry measurements and age.

**Statistical Analysis:** Linear regression (r) and Pearson correlation coefficients (r) were used to determine the relationships between lung anatomical position and 3He ADC measurements. All statistical analysis was performed using GraphPad Prism version 4.00 (GraphPad Software Inc, San Diego, CA, USA), results were considered statistically significant when the probability of making a Type I error was less than 5% (p < 0.05).

**Results:** Table 1 shows mean subject demographic characteristics, spirometry and hyperpolarized 3He ADC measurements for thirty-five healthy elderly never-smokers. The mean ADC ΔAP and ΔSI were 0.05 ± 0.03 cm²/s and 0.017 ± 0.017 cm²/s/cm, respectively. The mean AP-gradient and SI-gradient were -0.013 ± 0.008 cm²/s/cm and -0.002 ± 0.012 cm²/s/cm, respectively. The 3He ADC anterior-posterior gradient was statistically significant (r = -0.96, r² = 0.92, p = 0.009) (Figure 1A), but the 3He ADC superior-to-inferior gradient was not significant (r = 0.3, r² = 0.1, p = 0.8) (Figure 1B). The ratio of residual volume (RV) to total lung capacity (TLC) correlated significantly with the AP-gradient (r = 0.37, p = 0.03) (Figure 1D). There was no statistically significant relationship between age and ADC gradients (Figure 1C).

**Discussion:** There was a significant decrease in mean ADC from the most anterior to the posterior slices of the lung as expressed as ΔAP and AP-gradient due to compressible airspaces in healthy elderly never-smokers. AP ADC gradients were significantly correlated with RV/TLC which suggests regional gas trapping occurs in the healthy elderly. However, there was no significant correlation between the AP ADC gradients and age suggesting that regional gas trapping does not occur during the aging process for all subjects.

**Conclusions:** In a group of healthy elderly never-smokers, ADC anatomical differences in the anterior-posterior direction were significant and mean ADC was dependent on anterior-posterior location, but ADC gradients were not dependent on age.
