## Introduction

Previous functional magnetic resonance imaging (fMRI) studies have revealed substantial variation in the amplitude of the blood oxygenation level dependent (BOLD) response both across subjects and across brain regions and voxels within a subject. Although the source of this variability is not clear, growing evidence suggests the presence of significant vascular contributions, particularly through differences in baseline cerebral blood flow (CBF). For example, prior findings suggest that the BOLD response is inversely proportional to the baseline CBF [1] and venous oxygenation [2] across subjects (where venous oxygenation was found to be directly related to baseline CBF). Another study found the BOLD response is directly proportional to the baseline CBF across voxels [3]. These prior studies suggest that the relationship between the BOLD response and baseline CBF depends on the scale (per subject vs. per voxel) at which the signals are measured. In this study, we evaluate the mechanism by which the BOLD response depends on baseline CBF across subjects and voxels.

## Theory

We use the deoxyhemoglobin dilution model [4] to examine the relationship between the BOLD response and baseline CBF. In this model, the BOLD signal change is given by:

$$\Delta\text{BOLD}_a/\text{BOLD}_0 = M \left( 1 - (\text{CMRO}_{2a}/\text{CMRO}_{2_0})^\beta (\text{CBF}_a/\text{CBF}_0)^{\alpha-\beta} \right)$$

where  $M \equiv A \cdot (\text{CBF}_0)^\alpha (\text{OEF})^\beta$  is the maximum BOLD response,  $\text{CMRO}_2$  is the cerebral metabolic rate of oxygen metabolism,  $\beta$  is a deoxyhemoglobin exponent,  $\alpha$  is Grubb's exponent,  $A$  is a proportionality term representing scan and sample parameters,  $\text{OEF}$  is the oxygen extraction fraction, and the subscripts  $a$  and  $0$  indicate the active and baseline states, respectively. Within the framework of the model, here are two main mechanisms through which baseline CBF ( $\text{CBF}_0$ ) may influence the BOLD response. In the first mechanism,  $\text{CBF}_0$  may modulate the percent change in CBF ( $\% \Delta\text{CBF} = 100(\text{CBF}_a/\text{CBF}_0 - 1)$ ) as shown in a previous study [5]. In the second mechanism, changes in  $\text{CBF}_0$  modulate  $M$  through their effect on  $\text{OEF}$ , which is defined as  $\text{OEF} = (C_A \text{CMRO}_{2_0} / \text{CBF}_0)$  where  $C_A$  is the arterial concentration of oxygen.

## Methods

Ten subjects participated in the study after giving informed consent. Each experiment had: (a) a resting-state scan (8min 20s off), (b) two block design scans (60s on, 4 cycles of 20s on/60s off, 30s off; 8-Hz flickering checkerboard visual stimulus), (c) two hypercapnia scans (2min room air, 3min 5% CO<sub>2</sub>, 2min room air), and (d) CBF calibration scans. Subjects wore a non-rebreathing mask that could be connected to a 5% CO<sub>2</sub> gas mixture. Images were acquired on a 3T GE whole body system with a body transmit coil and an 8 channel receive head coil. Scans (a)-(c) were acquired with a PICORE QUIPSSII arterial spin labeling (ASL) sequence with dual echo spiral readout (TE1/TE2=2.9/24ms; T11/T12=600/1500ms; TR=2.5s). Six oblique axial 5-mm slices were prescribed about the calcarine sulcus for all runs. ASL data were calibrated to physiological units (mL/(100mg-min)). Data from the two block design runs were concatenated, and voxels that showed both CBF (1<sup>st</sup> echo;  $p < 0.05$ ) and BOLD (2<sup>nd</sup> echo;  $p < 0.05$ ) activation were used to form a region of interest (ROI) for each subject. Data were then analyzed by subject and by voxel:

**By Subject:** Data were averaged over the ROI of each subject, and the percent BOLD change ( $\% \Delta\text{BOLD}$ ) and  $\% \Delta\text{CBF}$  were computed for both the block design and hypercapnia scans. The maximum BOLD response ( $M$ ) for each subject was calculated from per subject  $\% \Delta\text{BOLD}$  and  $\% \Delta\text{CBF}$  hypercapnia values using the Davis model [4]. The per subject  $\text{CBF}_0$  values were calculated from the resting-state scan.

**By Voxel:** The per voxel  $\% \Delta\text{BOLD}$  and  $\% \Delta\text{CBF}$  were calculated for the block design and hypercapnia scans.  $M$  values were calculated from the hypercapnia values for each voxel. Per voxel  $\text{CBF}_0$  were computed from the resting-state scan. To overcome the low signal-to-noise of voxel-wise measurements, it was necessary to average data over bins based on voxel-wise  $\text{CBF}_0$  values. For voxels in the ROIs of each subject,  $\% \Delta\text{BOLD}$ ,  $\% \Delta\text{CBF}$ , and  $M$  values were sorted into five bins by their corresponding per voxel  $\text{CBF}_0$  values (bin thresholds (mL/(100g-min))): (1)  $>10$  to  $\leq 40$ , (2)  $>40$  to  $\leq 70$ , (3)  $>70$  to  $\leq 100$ , (4)  $>100$  to  $\leq 130$ , (5)  $>130$  to  $\leq 160$ ). The per voxel  $\% \Delta\text{BOLD}$ ,  $\% \Delta\text{CBF}$ , and  $M$  values were averaged within each  $\text{CBF}_0$  bin for each subject. In addition, we also averaged bin values across subjects.

## Results

**By Subject:** The figures in the top row show scatter plots of the per subject (a)  $\% \Delta\text{BOLD}$ , (b)  $\% \Delta\text{CBF}$ , and (c)  $M$  versus  $\text{CBF}_0$ , where all green lines in the figures denote linear fits. The  $\text{CBF}_0$  was significantly correlated to both  $\% \Delta\text{BOLD}$  ( $r = -0.78$ ,  $p = 0.008$ ) and  $\% \Delta\text{CBF}$  ( $r = -0.77$ ,  $p = 0.009$ ). However,  $M$  was not significantly correlated to  $\text{CBF}_0$  ( $p = 0.394$ ). Furthermore,  $\% \Delta\text{BOLD}$  was significantly correlated to  $\% \Delta\text{CBF}$  ( $r = 0.91$ ,  $p < 0.001$ ) but not  $M$  ( $p = 0.30$ ), suggesting that  $\% \Delta\text{CBF}$  is the main contributor to  $\text{CBF}_0$  related BOLD variability across subjects.

**By Voxel:** The figures in the bottom row show scatter plots of the per voxel (d)  $\% \Delta\text{BOLD}$ , (e)  $\% \Delta\text{CBF}$ , and (f)  $M$  values versus the five  $\text{CBF}_0$  bins for Subject 1, where the  $\text{CBF}_0$  bins are labeled by their midpoint  $\text{CBF}_0$  values, and vertical bars indicate standard error. Similar to the per subject data, per voxel  $\% \Delta\text{CBF}$  showed a significant negative correlation with  $\text{CBF}_0$  ( $r = -0.97$ ,  $p = 0.007$ ). In contrast to the per subject data, the per voxel  $\text{CBF}_0$  exhibited a significant positive correlation with both  $\% \Delta\text{BOLD}$  ( $r = 0.97$ ,  $p = 0.007$ ) and  $M$  ( $r = 0.96$ ,  $p = 0.009$ ). In addition, per voxel  $\% \Delta\text{BOLD}$  showed a positive correlation with per voxel  $M$  ( $r = 0.99$ ,  $p = 0.002$ ) and a negative correlation with per voxel  $\% \Delta\text{CBF}$  ( $r = -0.91$ ,  $p = 0.034$ ), indicating that either  $M$  or  $\% \Delta\text{CBF}$  may contribute to  $\text{CBF}_0$  related BOLD variability across voxels. When the voxel-wise data was averaged in bins across subjects,  $\text{CBF}_0$  was significantly correlated to the  $\% \Delta\text{BOLD}$  ( $r = 0.99$ ,  $p = 0.002$ ),  $\% \Delta\text{CBF}$  ( $r = -0.93$ ,  $p = 0.02$ ), and  $M$  ( $r = 0.98$ ,  $p = 0.002$ ) values, indicating that voxel-wise trends found in Subject 1 are also representative of the remaining subjects.

## Discussion

Our results suggest that variations in  $\text{CBF}_0$  across subjects affect the BOLD response mainly through the dependence of  $\% \Delta\text{CBF}$  on  $\text{CBF}_0$ . In contrast, variations in  $\text{CBF}_0$  across voxels appear to modulate the BOLD response through the dependence of  $M$  on  $\text{CBF}_0$ . Although  $\% \Delta\text{CBF}$  also showed a dependence on  $\text{CBF}_0$  across voxels, the decrease in  $\% \Delta\text{CBF}$  with increased  $\text{CBF}_0$  is unlikely to have given rise to the observed increase in  $\% \Delta\text{BOLD}$  with increases in  $\text{CBF}_0$ . The inverse correlation between  $M$  and  $\text{CBF}_0$  across voxels indicates that the  $\text{OEF}$  may be relatively independent of  $\text{CBF}_0$  across voxels, reflecting a tight coupling between  $\text{CMRO}_{2_0}$  and  $\text{CBF}_0$  that is consistent with the conclusions of a previous study [6]. In contrast, the lack of significant correlation between  $M$  and  $\text{CBF}_0$  across subjects suggests that the  $\text{OEF}$  may be inversely related to  $\text{CBF}_0$  across subjects. These findings shed light on the basic mechanisms of the BOLD signal and suggest that different factors should be considered in the interpretation of the BOLD response when analyzing data across subjects versus across voxels.
