PURPOSE

Left ventricular (LV) diastolic chamber stiffness ($\beta$) provides key information about LV diastolic properties. Single beat method, based on single LV pressure measurement and corresponding LV volumes, has been proposed to derive LV diastolic chamber stiffness. Due to incomplete left ventricular (LV) relaxation, relaxation time constant $\tau$ is used to correct for this pressure in computing LV diastolic chamber stiffness. It is extremely important to identify the minimum pressure and corresponding LV pressure which are crucial for defining the true/corrected $\beta$. However $\tau$ is affected by heart rate and indirectly by LV end-diastolic pressure (LVEDP). Further there are multiple methodologies for calculating $\tau$, including mono-exponential method and hybrid logistic method, resulting in various $\tau$ values. Therefore, the corrected minimum pressure and volume corresponding to 3.5-4, where LV is considered completely relaxed, may not always be reliable. There is even debate about true $\tau$ value where the LV is considered relaxed. Therefore single beat approach that is independent of $\tau$ and incorporates true volumetric data to calculate corrected $\beta$ will be attractive to define diastolic physiology especially in patients with suspected diastolic heart failure. Here we propose a novel single beat approach to corrected LV diastolic chamber stiffness independent of $\tau$ that utilizes cMRI LV volumetric measurements.

METHODS

Twenty-six patients with normal LVEF and no acute myocardial infarction are studied using high-fidelity pressure measurement and cMRI. cMRI was performed on a 1.5-T MRI scanner (Signa, GE Healthcare, Milwaukee, Wisconsin) optimized for cardiac imaging. The electrocardiographically gated breath-hold steady-state free precision technique was used to obtain standard (2-, 3-, and 4-chamber long axis or 360° long axis and serial parallel short-axis) views using the following typical parameters: slice thickness of the imaging planes 8 mm, field of view 40cm, scan matrix 256 x 128, flip angle 45°, repetition/echo times 3.8/1.6 ms.

The measured chamber stiffness is computed as the stiffness constant $\beta_m$ from LV diastolic pressure-volume ($P$-$V$) relationship $P = \alpha e^{\beta_m V}$, fitted by 3 pairs of $P$-$V$ coordinates: $P$-$V$ at the time of minimum pressure ($P_{min}$), pre-atrial kick $P$-$V$, and LV end-diastolic $P$-$V$. To avoid using inaccurate $P_{min}$ and volume due to abnormally slow relaxation, corrected diastolic chamber stiffness $\beta_c$ is computed by replacing the first pair of $P$-$V$ coordinates at the time of $P_{min}$ to $P_0 - V_0$ at $P \approx 0\text{mmHg}$, $V_0 = \text{LV EDV}(0.6 - 0.006\text{LVEDP})$ and $P_0 = \alpha V_0^\beta$, where $\alpha$ and $\beta$ were previously defined [6]. Volume at $P=15\text{mmHg}$, denoted as $V_{15}$ is computed using the fitted model.

RESULTS

Although $\beta_c$ is correlated with $\beta_m$ ($r=0.45, P=0.022$), it is significantly greater than $\beta_m$ ($0.027\pm0.01$ vs $0.012\pm0.006, P<0.0001$). $\beta_c$ also significantly correlates negatively with $V_{15}$ ($r=-0.53, P=0.016$) and correlates positively with log(LVEDP)/LVEDV ($r=0.39, P=0.04$), which is consistent with the theoretical model. The mean $\beta_c$ and $\beta_m$ curves are depicted in the figure.

DISCUSSIONS AND CONCLUSIONS

The corrected LV diastolic chamber stiffness $\beta_c$, incorporating $P_0 - V_0$ at the time of $P \approx 0\text{mmHg}$, is obtained independent of $\tau$. It provides evaluation of LV passive filling property that is not affected by incomplete relaxation and is relatively simple to measure that utilizes routinely obtained LV pressure and volume measurement from cMRI.
